ABSTRACT—In previous studies on Am(III)/Nd(III) interactions with borate, the borate concentrations were kept at a relatively low level, up to ~0.16 mol•kg$^{-1}$ as the highest. Such concentrations of borate are not saturated, in terms of borate, with borate-bearing phases such as borax (Na$_2$B$_4$O$_7$•10H$_2$O) and tincalconite (Na$_2$B$_4$O$_5$•5H$_2$O) that could be present in geological repositories. For instance, tincalconite has been observed as a corrosion product for boroslicate glass for HLW under the repository conditions in China.

In this study, we examine the Nd(III) interactions with borate in equilibrium with borax in a wide range of NaCl solutions at 25°C. In our experiments, the solubility-controlling phase for Nd(III) is Nd(OH)$_3$(micro cr). In synthesis of Nd(OH)$_3$(micro cr), we followed the procedure from literature. Our results indicate that high borate concentrations (~0.5 mol•kg$^{-1}$) in 0.01 and 0.1 mol•kg$^{-1}$ NaCl solutions have an obvious effect on Nd(III). At such a high concentration of borate, borate can enhance the solubility of Nd(OH)$_3$(micro cr), or NdB$_4$O$_7$(OH)$_3$(cr) may control the solubility.

1. Introduction

Borate is important to geological processes, although boron is the 41st abundant element in the Earth’s Crust, lower than the abundances of rare earth elements such as Nd, which is the 28th abundant element. In natural groundwaters such as brines associated with salt formations, there may be relatively high concentrations of borate [1]. In addition, when boroslicate glass for high level nuclear waste (HLW) is corroded, borate is also released into the groundwater [2-3]. Borate can impact nuclear waste management in two aspects. First of all, borate can form an aqueous complex with Nd(III) and Eu(III) [4-6], analogs to actinides in +III oxidation state, such as Am(III). Therefore, borate could become a potential transport agent for actinides if the Am(III)-borate complex contributes significantly to the total Am(III) concentrations. In the second aspect, numerous actinide borates have recently been successfully synthesized [7-8], including a Pu(III) borate, Pu$_2$[B$_3$O$_{10}$(OH)$_2$Br$_2$(H$_2$O)$_3$]•0.5H$_2$O, in addition to the well known lanthanide borates such as NdB$_4$O$_{13}$(OH)$_2$ [9]. This implies that actinides in waste could be transformed into, or be sequestered as, actinide borates, if their solubility limits are reached.

Actinides in +III state represented by Am(III) are present in nuclear waste in geological repositories. Therefore, the interactions between Am(III) and borate are important for performance assessment (PA) for geological repositories for nuclear wastes. As an example, in the Waste Isolation Pilot Plant (WIPP), a U.S. DOE geological repository for defense-related transuranic (TRU) waste in the bedded salt formations in New Mexico, USA, the inventory of Am(III) in waste was 143 kg for the WIPP Compliance Application Re-Certification in 2009 (CRA-2009). The borate concentrations in the two WIPP brines that are important for performance assessment (PA), i.e., Generic Weep Brine (GWB), and Energy Research and Development Administration (WIPP Well) 6 (ERDA-6), are 0.180 mol•kg$^{-1}$ and 0.0692 mol•kg$^{-1}$ [10], respectively.

In the previous studies on Am(III)/Nd(III) interactions with borate, the borate concentrations were kept at the relatively low level, and up to ~0.16 mol•kg$^{-1}$ as the highest (i.e., [4, 9]). Such concentrations of borate are not saturated, in terms of borate, with borate-bearing phases such as borax (Na$_2$B$_4$O$_7$•10H$_2$O) and tincalconite (Na$_2$B$_4$O$_5$•5H$_2$O) that could be present in geological repositories. For instance, tincalconite has been observed as one of corrosion products for boroslicate glass for HLW under the repository conditions in China [11]. The borate concentrations saturated with borax and
tincalconite are much higher than 0.16 mol·kg⁻¹, especially in solutions with low concentrations of sodium. For example, the borate concentrations are ~0.5 mol·kg⁻¹ in 0.01 mol·kg⁻¹, NaCl [12]. Therefore, the Am(III)/Nd(III) interactions with borate need to be further studied, especially in high borate concentrations.

2. Methods and Results

In this section we describe the experimental methodology used in this study.

2.1 Synthesis of Starting Material

As detailed in Wood et al. [13], many other synthesis methods suffer from various shortcomings, which would result in difficulty/uncertainty interpreting solubility data. Therefore, starting with well-defined high-purity material is of fundamental importance to the success of solubility experiments. In synthesis of Nd(OH)₃(micro cr), high purity Nd₂O₃ was first loaded into Paar® reaction vessels with deaerated DI water, and then the reaction vessels were sealed in a glovebox under a positive pressure of an inert gas. The reaction vessels were then removed from the glovebox and placed into a muffle furnace. Nd(OH)₃(micro cr) was synthesized by reacting the high purity Nd₂O₃ with the deaerated DI water at 473.15 K in Paar® reaction vessels for a period of two weeks. Following the synthesis step, the reaction vessels were then transferred back into the glovebox, and were opened for drying in an atmosphere of inert gas. This synthesis method assures the complete conversion of Nd₂O₃ to Nd(OH)₃(micro cr), as demonstrated by XRD and SEM-EDS characterizations. The SEM-EDS characterization shows that the size of crystals is small, and the majority of crystals are around micrometer or sub-micrometer in size, as indicated by SEM-EDS images (Figure 1A and 1B). As shown by the XRD analysis, the synthetic neodymium has a well-defined XRD pattern (Figure 2) that is indicative of a crystalline phase. Therefore, we term our synthetic neodymium hydroxide as “micro crystalline neodymium hydroxide”, Nd(OH)₃(micro cr), throughout the entire paper. Figure 2 shows that the XRD pattern of synthetic Nd(OH)₃(micro cr) produced by this work has the exact match with the reference standard of Nd(OH)₃(cr) from the International Center of Diffraction Data (ICDD).

Of note, the deaerated DI water used in the synthesis was prepared by vigorously bubbling high purity Ar or N₂ gas through DI water for a minimum of 30 minutes in the glovebox, following a similar procedure used by Xiong [14]. This deaeration process was intended to remove any dissolved CO₂ and therefore ensure the synthesis process was not contaminated by carbonate.

2.2 Experimental Setup

Undersaturation experiments are conducted at 298.15 ± 0.5 K. In our solubility experiments, approximately 0.3 grams of Nd(OH)₃(micro cr) and about 10 grams of Na₂B₄O₇·10H₂O (borax) were placed into serum bottles along with 100 mL of supporting solutions with the desired ionic strength. The supporting solutions consisted of 0.01, 0.1, 1.0, 2.1, 3.2, 4.4 and 5.0 mol·kg⁻¹ NaCl solutions where mol·kg⁻¹ refers to concentration on molar scale, i.e., moles per 1000 g of water. All supporting solutions were prepared from reagent grade chemicals from Fisher Scientific, or its associated vendors, and deaerated DI water.

Solution samples were periodically withdrawn from the experiments to determine if the system had reached equilibrium. Before each sampling, pH readings were taken for each experiment. In each sampling, about 3 mL of solution samples were taken from each experiment, and the solution samples were filtered through a 0.2 μm filter, and transferred into pre-weighed 10 mL Grade A volumetric flasks. After filtration, masses of each solution sample were determined with a balance precise to the fourth decimal place. Samples were then immediately acidified with 0.5 mL of the Optima® Grade HNO₃ from Fisher Scientific, and diluted to 10 mL with DI water. Prior to chemical analyses for Nd using the PerkinElmer NexION 300D ICP-MS, and for Na using the PerkinElmer Optima 3300 Dual View (DV) ICP-AES, aliquots from the afore-mentioned acidified samples were further diluted to an appropriate ionic strength.

The pH readings were measured with an Orion-Ross combination pH glass electrode, coupled with an Orion Research EA 940 pH meter that was calibrated with three pH buffers (pH 4, pH 7, and pH 10). The measured pH readings were converted to negative logarithm of hydrogen ion concentrations on molar scale (i.e., pcH) following
the procedure detailed in Xiong [14] and Xiong and Lord [10], and pH’s were converted to \( \text{pH}_m \)'s (negative logarithm of hydrogen ion concentrations on molar scale) according to the equations in Xiong et al. [15].

### 2.3 Experimental Results

Our experimental results are displayed in Figures 3-5. In Figures 3-5, our experimental results are compared with the predicted values for Am(OH)\(_3\)(s) and AmB\(_9\)O\(_{13}\)(OH)\(_4\)(cr) which were calculated using EQ3/6 Version 8.0a, and the thermodynamic database data0.fm2. Note the dashed and dotted lines in Figures 3-5 represent the EQ3/6 simulated concentrations, and the symbols are the measured data. They are produced using EQ3/6 Version 8.0a [16-17] with the database data0.fm2 [18-19]. EQ3/6 Version 8.0a has been extensively used in the previous publications [e.g., 20-23]. The equilibrium constant for AmB\(_9\)O\(_{13}\)(OH)\(_4\)(cr) at 25°C is from [24].

Figure 3 shows that there are relatively high concentrations of Nd(III) in the experiments in 0.01 and 0.1 mol·kg\(^{-1}\) NaCl. Of note, the borate concentrations saturated with borax in these two experiments are 0.53 and 0.42 mol·kg\(^{-1}\), respectively. The Nd(III) concentrations without the species AmHB\(_4\)O\(_7\)\(^{2+}\) are higher than those predicted for Am(OH)\(_3\)(s), but are close to those predicted for AmB\(_9\)O\(_{13}\)(OH)\(_4\)(cr). This may suggest that borate enhances the solubility of Am(OH)\(_3\)(s), or AmB\(_9\)O\(_{13}\)(OH)\(_4\)(cr) controls the solubility.

Figure 4 displays the results in 1.0 and 2.1 mol·kg\(^{-1}\) NaCl. In these two experiments, the borate concentrations are 0.22 and 0.18, respectively. Again, the Nd(III) concentrations are higher than those predicted for Am(OH)\(_3\)(s), but are close to those for AmB\(_9\)O\(_{13}\)(OH)\(_4\)(cr).

The results in 3.2, 4.4, and 5.0 mol·kg\(^{-1}\) appear in Figure 5. The Nd(III) concentrations are close to those predicted for Am(OH)\(_3\)(s). It implies that the role that borate plays to enhance the solubility of Am(OH)\(_3\)(s) is less at high NaCl concentrations. The borate concentrations in these experiments are 0.20, 0.16 and 0.16 mol·kg\(^{-1}\), respectively.

It is of interest to note that the data from Hinz et al. [9] for NdB\(_9\)O\(_{13}\)(OH)\(_4\)(cr) at pH\(_m\) ~9 are close to those predicted for Am(OH)\(_3\)(s). As indicated by Figure 5, NdB\(_9\)O\(_{13}\)(OH)\(_4\)(cr) could be converted to the hydroxide form in high pH\(_m\) region.
3. Conclusions

We have conducted solubility measurements regarding \( \text{Nd(OH)}_3 \) (micro cr) in NaCl solutions saturated with borax at 25°C. Our results indicate that high borate concentrations (~0.5 mol•kg\(^{-1}\)) in NaCl solutions have an obvious effect on Nd(III). At such a high concentration of borate, borate can enhance the solubility of Nd(OH)\(_3\) (micro cr), or NdB\(_9\)O\(_{13}\)(OH)\(_4\) (cr) may control the solubility.
